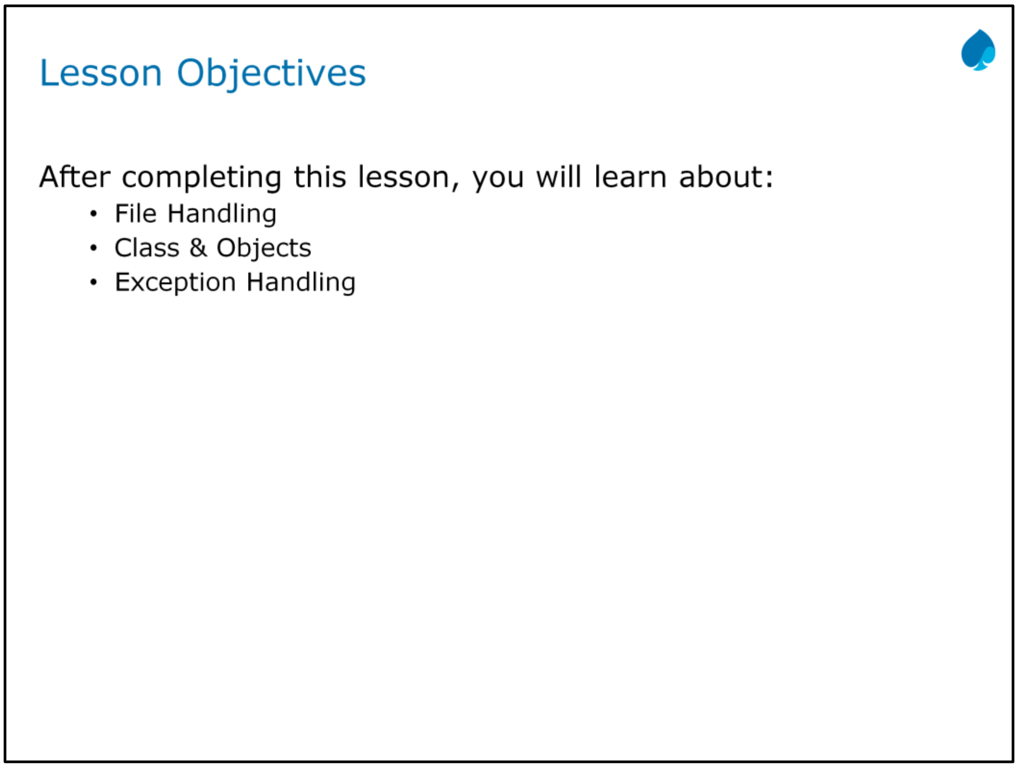
Python

Lesson 04 File Handling, Classes & Objects, Exception Handling

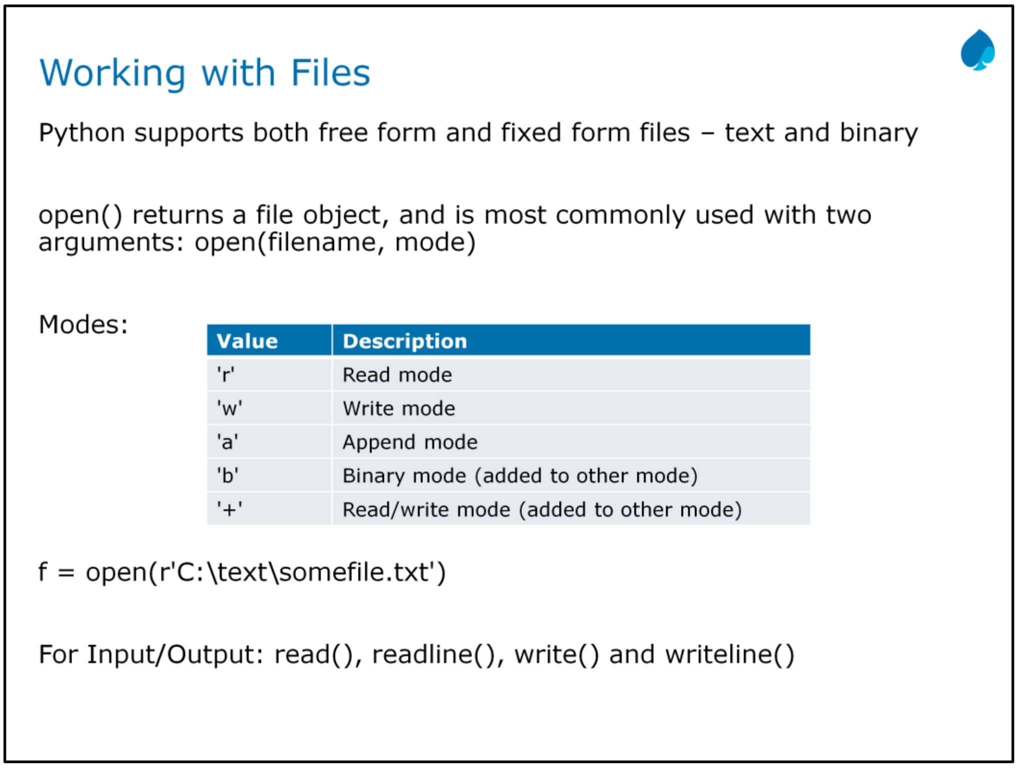
Instructor Notes:



Lesson Objectives

After completing this lesson, you will learn about:
- File Handling
- Class & Objects
- Exception Handling

Instructor Notes:



Working with Files

Python supports both free form and fixed form files – text and binary

open() returns a file object, and is most commonly used with two arguments: open(filename, mode)

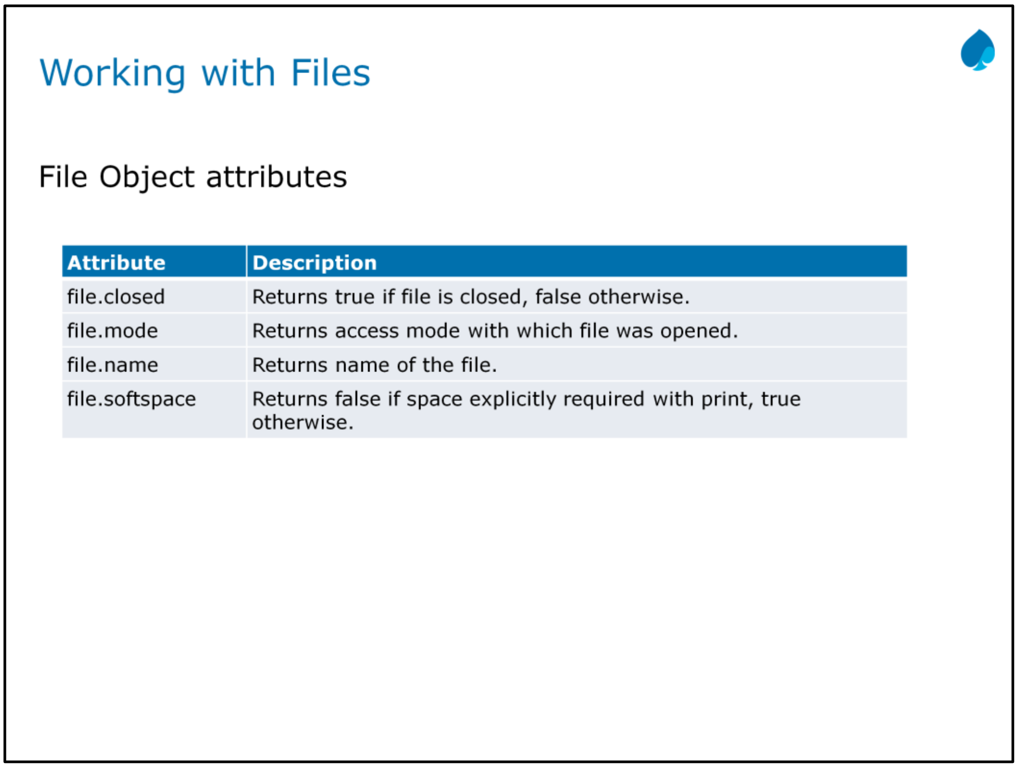
Modes:

Value	Description
'r'	Read mode
'w'	Write mode
'a'	Append mode
'b'	Binary mode (added to other mode)
'+'	Read/write mode (added to other mode)

```
f = open(r'C:\text\somefile.txt')
```

For Input/Output: read(), readline(), write() and writeline()

Instructor Notes:

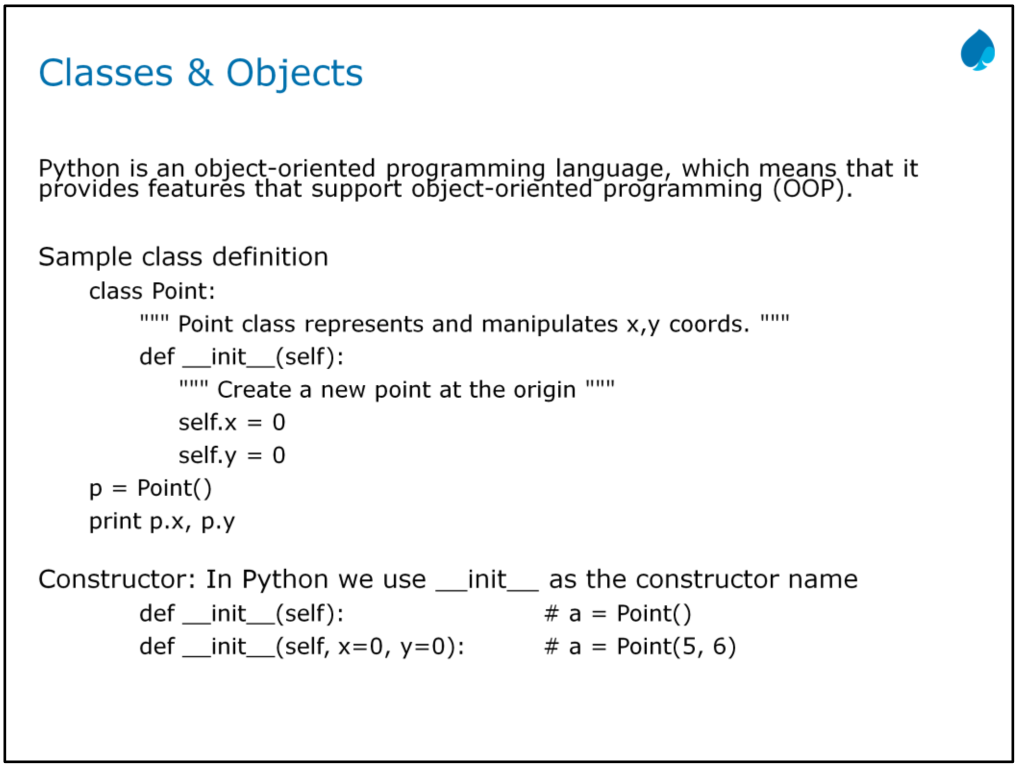


Working with Files

File Object attributes

Attribute	Description
file.closed	Returns true if file is closed, false otherwise.
file.mode	Returns access mode with which file was opened.
file.name	Returns name of the file.
file.softspace	Returns false if space explicitly required with print, true otherwise.

Instructor Notes:



Classes & Objects

Python is an object-oriented programming language, which means that it provides features that support object-oriented programming (OOP).

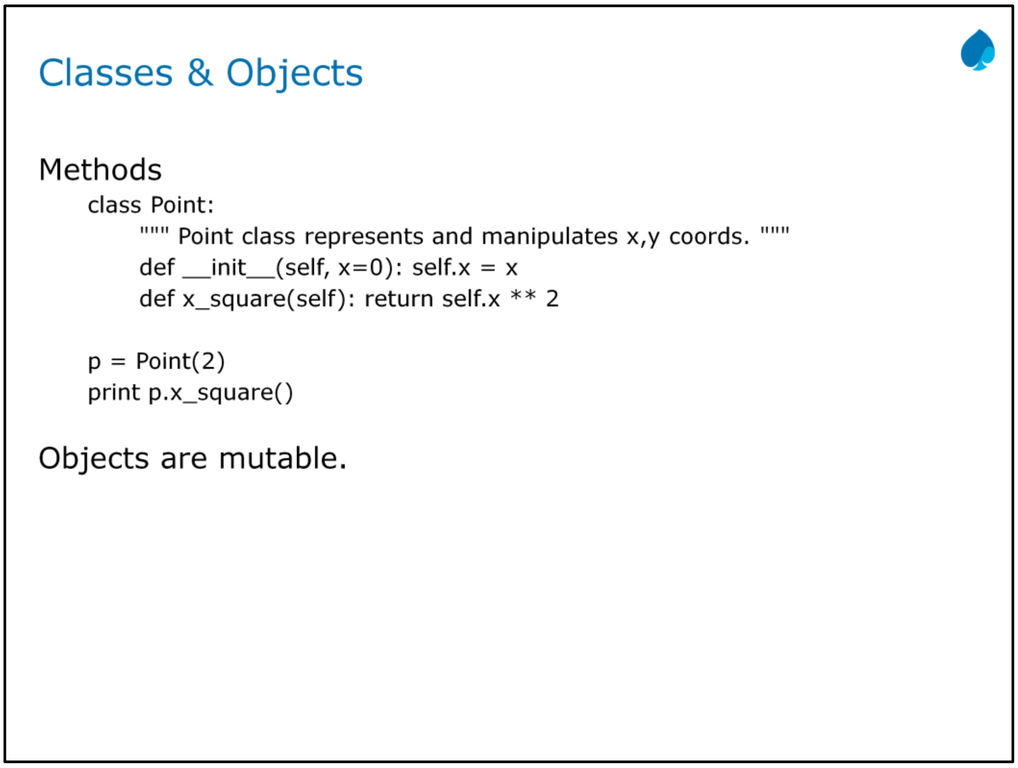
Sample class definition

```
class Point:
    """ Point class represents and manipulates x,y coords. """
    def __init__(self):
        """ Create a new point at the origin """
        self.x = 0
        self.y = 0
p = Point()
print p.x, p.y
```

Constructor: In Python we use __init__ as the constructor name

```
    def __init__(self):                # a = Point()
    def __init__(self, x=0, y=0):      # a = Point(5, 6)
```

Instructor Notes:



Classes & Objects

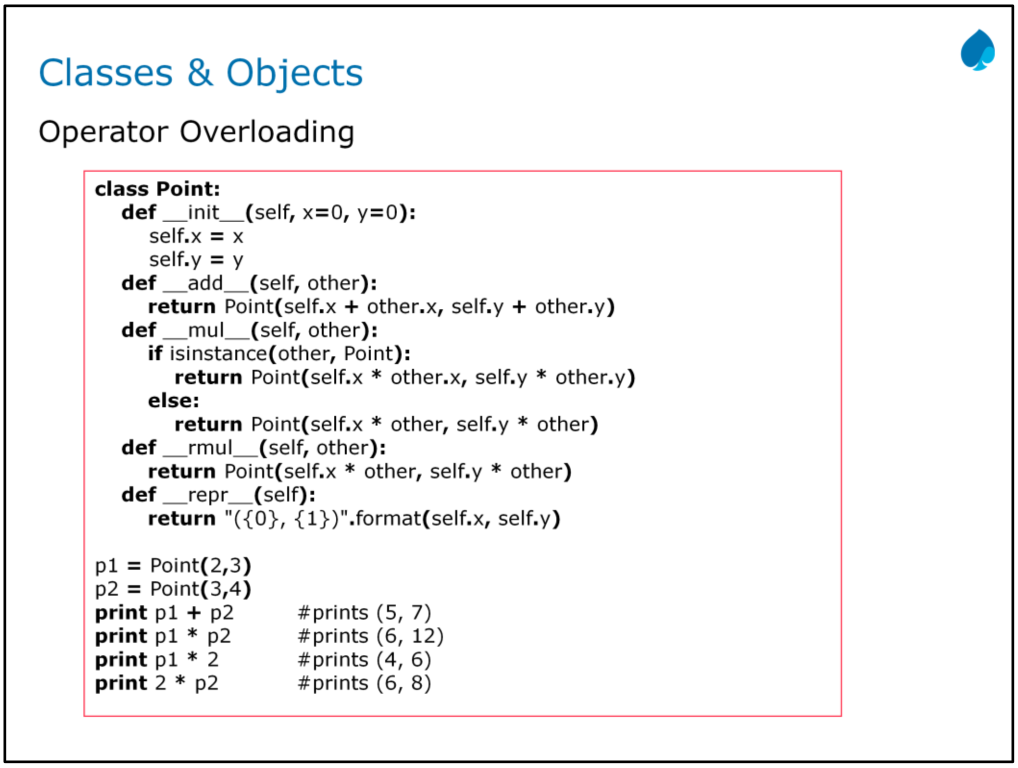
Methods

```
class Point:
    """ Point class represents and manipulates x,y coords. """
    def __init__(self, x=0): self.x = x
    def x_square(self): return self.x ** 2

p = Point(2)
print p.x_square()
```

Objects are mutable.

Instructor Notes:



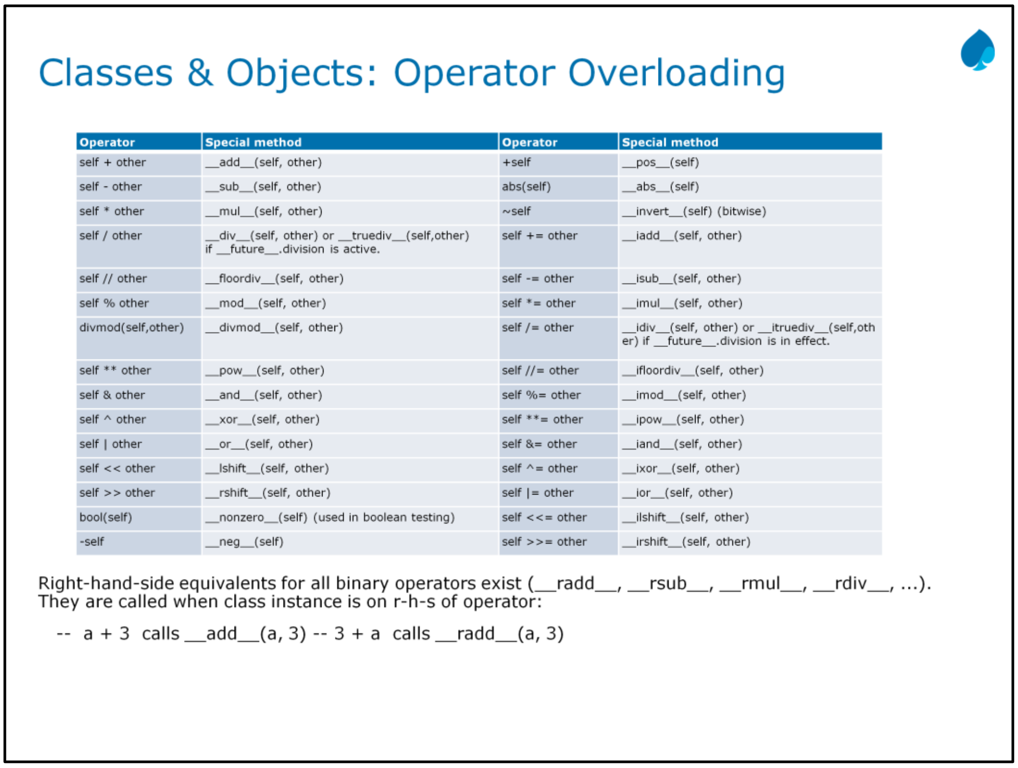
Classes & Objects

Operator Overloading

```
class Point:
    def __init__(self, x=0, y=0):
        self.x = x
        self.y = y
    def __add__(self, other):
        return Point(self.x + other.x, self.y + other.y)
    def __mul__(self, other):
        if isinstance(other, Point):
            return Point(self.x * other.x, self.y * other.y)
        else:
            return Point(self.x * other, self.y * other)
    def __rmul__(self, other):
        return Point(self.x * other, self.y * other)
    def __repr__(self):
        return "({0}, {1})".format(self.x, self.y)

p1 = Point(2,3)
p2 = Point(3,4)
print p1 + p2        #prints (5, 7)
print p1 * p2        #prints (6, 12)
print p1 * 2         #prints (4, 6)
print 2 * p2         #prints (6, 8)
```

Instructor Notes:



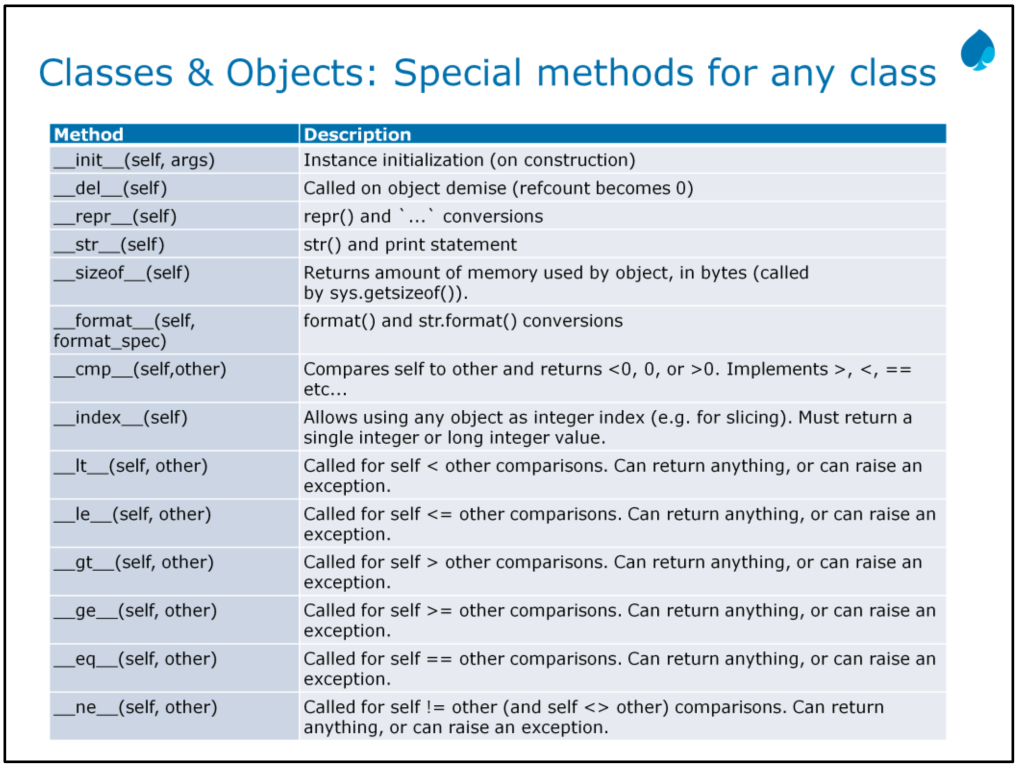
Classes & Objects: Operator Overloading

Operator	Special method	Operator	Special method
self + other	__add__(self, other)	+self	__pos__(self)
self - other	__sub__(self, other)	abs(self)	__abs__(self)
self * other	__mul__(self, other)	~self	__invert__(self) (bitwise)
self / other	__div__(self, other) or __truediv__(self,other) if __future__.division is active.	self += other	__iadd__(self, other)
self // other	__floordiv__(self, other)	self -= other	__isub__(self, other)
self % other	__mod__(self, other)	self *= other	__imul__(self, other)
divmod(self,other)	__divmod__(self, other)	self /= other	__idiv__(self, other) or __itruediv__(self,other) if __future__.division is in effect.
self ** other	__pow__(self, other)	self //= other	__ifloordiv__(self, other)
self & other	__and__(self, other)	self %= other	__imod__(self, other)
self ^ other	__xor__(self, other)	self **= other	__ipow__(self, other)
self | other	__or__(self, other)	self &= other	__iand__(self, other)
self << other	__lshift__(self, other)	self ^= other	__ixor__(self, other)
self >> other	__rshift__(self, other)	self |= other	__ior__(self, other)
bool(self)	__nonzero__(self) (used in boolean testing)	self <<= other	__ilshift__(self, other)
-self	__neg__(self)	self >>= other	__irshift__(self, other)

Right-hand-side equivalents for all binary operators exist (__radd__, __rsub__, __rmul__, __rdiv__, ...).
They are called when class instance is on r-h-s of operator:

-- a + 3 calls __add__(a, 3) -- 3 + a calls __radd__(a, 3)

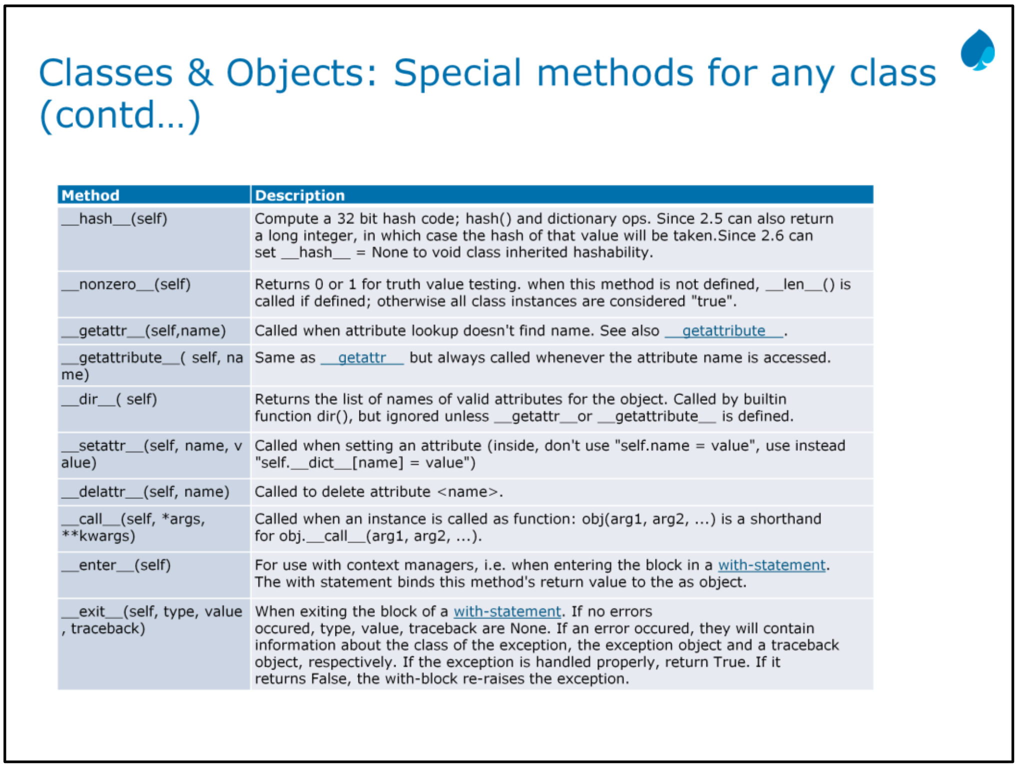
Instructor Notes:



Classes & Objects: Special methods for any class

Method	Description
__init__(self, args)	Instance initialization (on construction)
__del__(self)	Called on object demise (refcount becomes 0)
__repr__(self)	repr() and `…` conversions
__str__(self)	str() and print statement
__sizeof__(self)	Returns amount of memory used by object, in bytes (called by sys.getsizeof()).
__format__(self, format_spec)	format() and str.format() conversions
__cmp__(self,other)	Compares self to other and returns <0, 0, or >0. Implements >, <, == etc…
__index__(self)	Allows using any object as integer index (e.g. for slicing). Must return a single integer or long integer value.
__lt__(self, other)	Called for self < other comparisons. Can return anything, or can raise an exception.
__le__(self, other)	Called for self <= other comparisons. Can return anything, or can raise an exception.
__gt__(self, other)	Called for self > other comparisons. Can return anything, or can raise an exception.
__ge__(self, other)	Called for self >= other comparisons. Can return anything, or can raise an exception.
__eq__(self, other)	Called for self == other comparisons. Can return anything, or can raise an exception.
__ne__(self, other)	Called for self != other (and self <> other) comparisons. Can return anything, or can raise an exception.

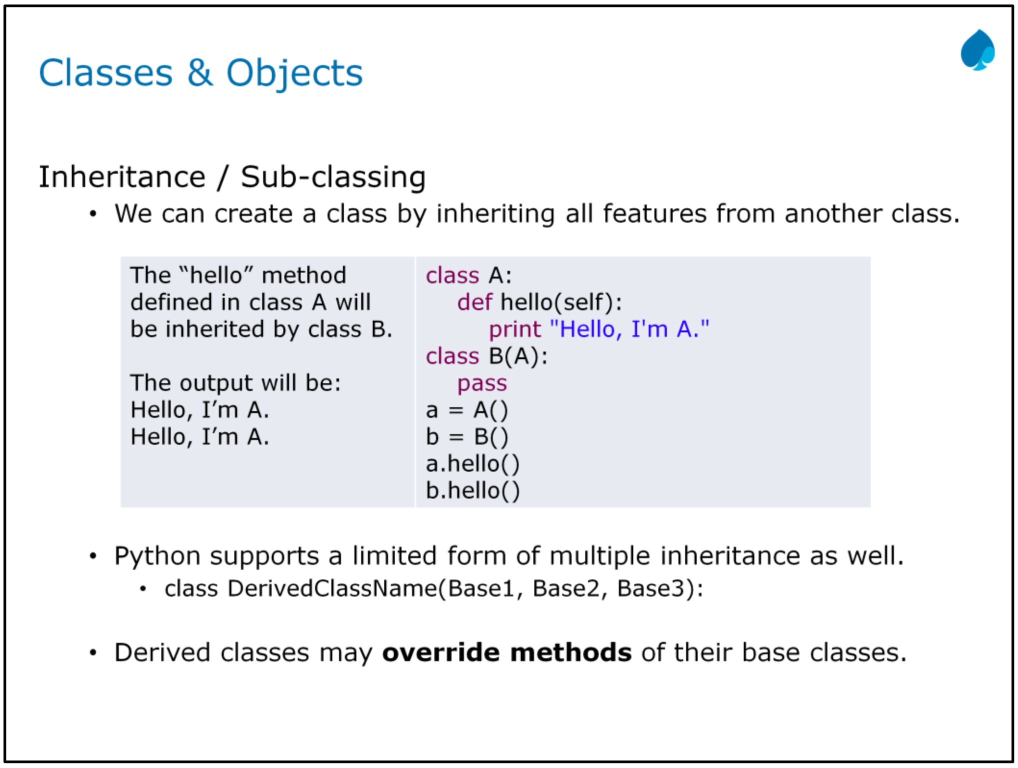
Instructor Notes:



Classes & Objects: Special methods for any class (contd...)

Method	Description
__hash__(self)	Compute a 32 bit hash code; hash() and dictionary ops. Since 2.5 can also return a long integer, in which case the hash of that value will be taken.Since 2.6 can set __hash__ = None to void class inherited hashability.
__nonzero__(self)	Returns 0 or 1 for truth value testing. when this method is not defined, __len__() is called if defined; otherwise all class instances are considered "true".
__getattr__(self,name)	Called when attribute lookup doesn't find name. See also __getattribute__.
__getattribute__(self, name)	Same as __getattr__ but always called whenever the attribute name is accessed.
__dir__(self)	Returns the list of names of valid attributes for the object. Called by builtin function dir(), but ignored unless __getattr__or __getattribute__ is defined.
__setattr__(self, name, value)	Called when setting an attribute (inside, don't use "self.name = value", use instead "self.__dict__[name] = value")
__delattr__(self, name)	Called to delete attribute <name>.
__call__(self, *args, **kwargs)	Called when an instance is called as function: obj(arg1, arg2, ...) is a shorthand for obj.__call__(arg1, arg2, ...).
__enter__(self)	For use with context managers, i.e. when entering the block in a with-statement. The with statement binds this method's return value to the as object.
__exit__(self, type, value , traceback)	When exiting the block of a with-statement. If no errors occured, type, value, traceback are None. If an error occured, they will contain information about the class of the exception, the exception object and a traceback object, respectively. If the exception is handled properly, return True. If it returns False, the with-block re-raises the exception.

Instructor Notes:



Classes & Objects

Inheritance / Sub-classing

- We can create a class by inheriting all features from another class.

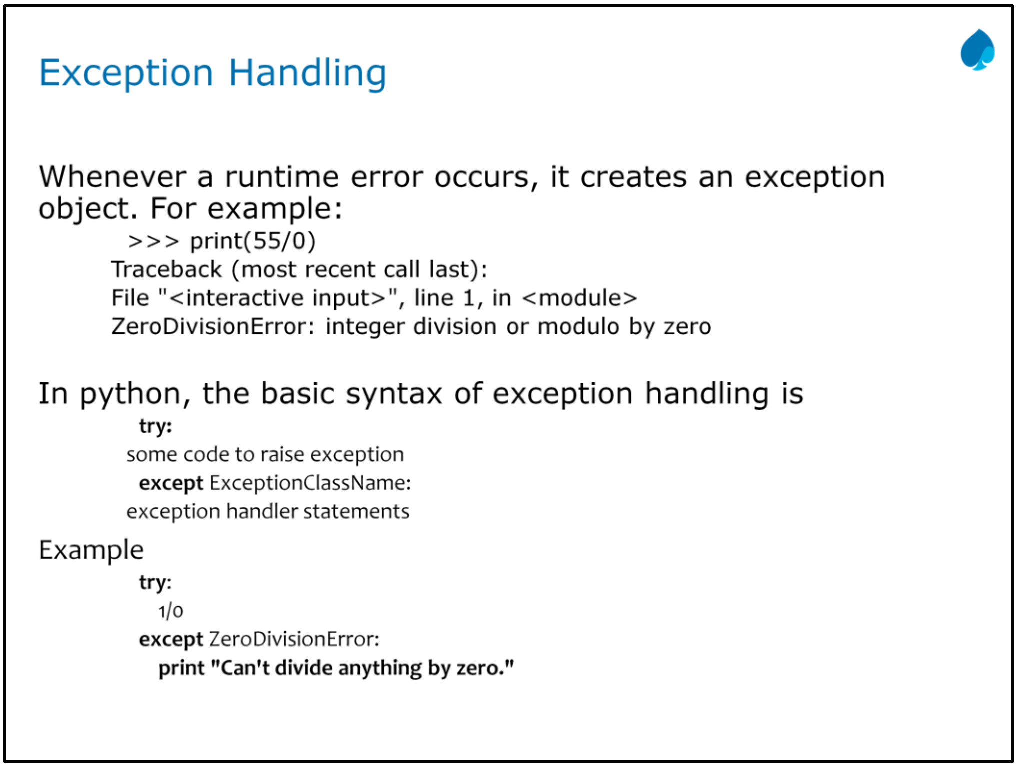
The “hello” method defined in class A will be inherited by class B.

The output will be:
Hello, I’m A.
Hello, I’m A.

```
class A:
    def hello(self):
        print "Hello, I'm A."
class B(A):
    pass
a = A()
b = B()
a.hello()
b.hello()
```

- Python supports a limited form of multiple inheritance as well.
  - class DerivedClassName(Base1, Base2, Base3):
- Derived classes may **override methods** of their base classes.

Instructor Notes:



Exception Handling

Whenever a runtime error occurs, it creates an exception object. For example:

```
 >>> print(55/0)
Traceback (most recent call last):
File "<interactive input>", line 1, in <module>
ZeroDivisionError: integer division or modulo by zero
```

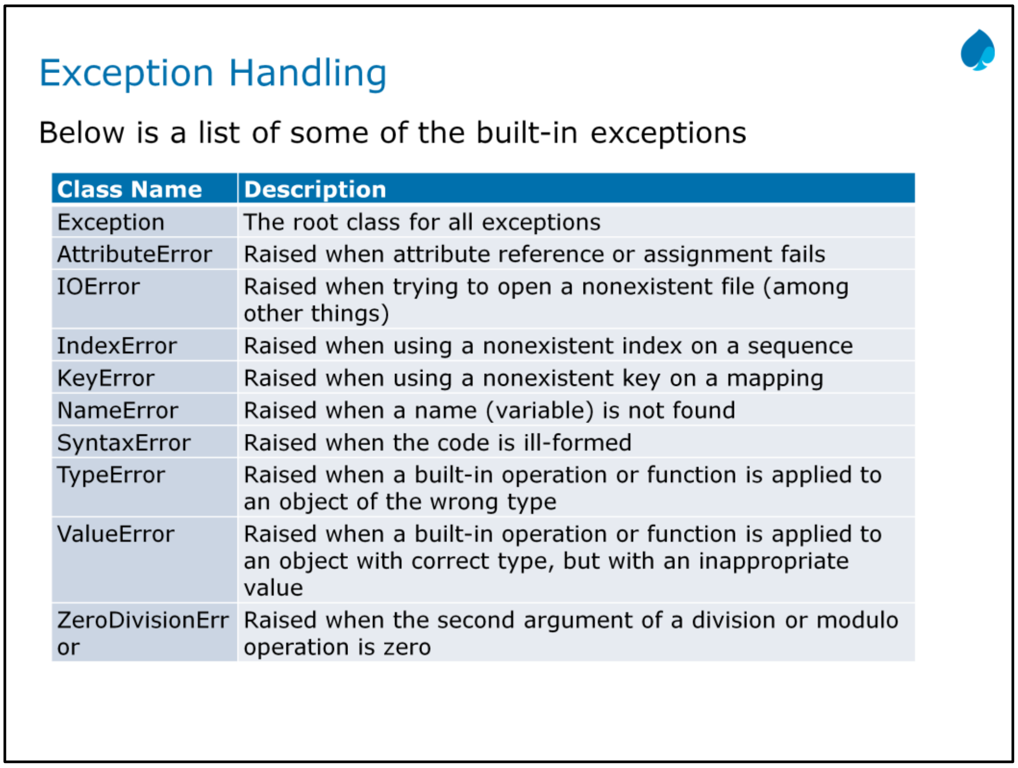
In python, the basic syntax of exception handling is

```
 try:
some code to raise exception
 except ExceptionClassName:
exception handler statements
```

Example

```
try:
  1/0
except ZeroDivisionError:
  print "Can't divide anything by zero."
```

Instructor Notes:

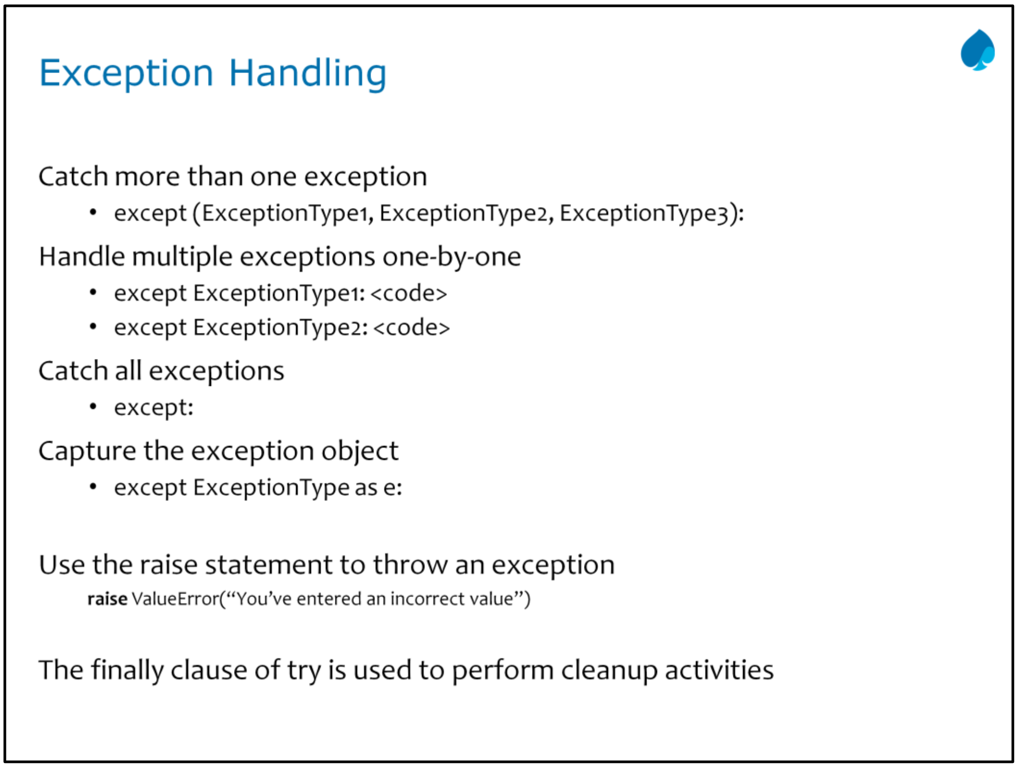


Exception Handling

Below is a list of some of the built-in exceptions

Class Name	Description
Exception	The root class for all exceptions
AttributeError	Raised when attribute reference or assignment fails
IOError	Raised when trying to open a nonexistent file (among other things)
IndexError	Raised when using a nonexistent index on a sequence
KeyError	Raised when using a nonexistent key on a mapping
NameError	Raised when a name (variable) is not found
SyntaxError	Raised when the code is ill-formed
TypeError	Raised when a built-in operation or function is applied to an object of the wrong type
ValueError	Raised when a built-in operation or function is applied to an object with correct type, but with an inappropriate value
ZeroDivisionError	Raised when the second argument of a division or modulo operation is zero

Instructor Notes:



Exception Handling

Catch more than one exception

- except (ExceptionType1, ExceptionType2, ExceptionType3):

Handle multiple exceptions one-by-one

- except ExceptionType1: <code>
- except ExceptionType2: <code>

Catch all exceptions

- except:

Capture the exception object

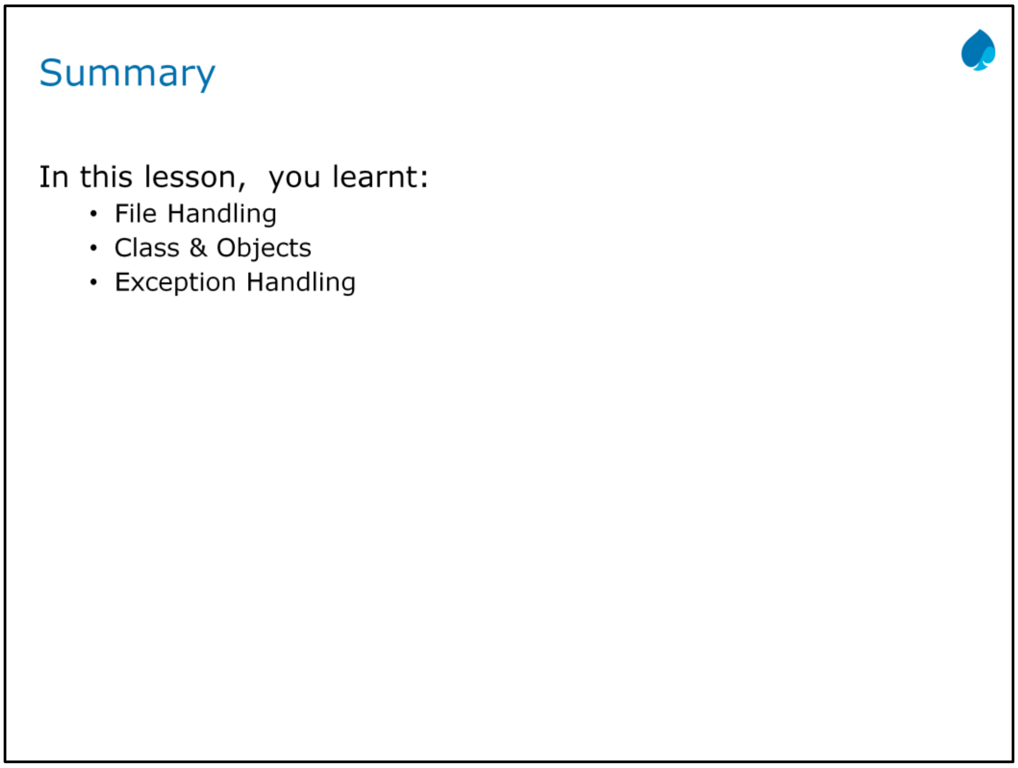
- except ExceptionType as e:

Use the raise statement to throw an exception

raise ValueError(“You’ve entered an incorrect value”)

The finally clause of try is used to perform cleanup activities

Instructor Notes:



Summary

In this lesson, you learnt:

- File Handling
- Class & Objects
- Exception Handling
